Abstract

In ensemble (or bulk) quantum computation, measurements of qubits in an individual computer cannot be performed. Instead, only expectation values can be measured. As a result of this limitation on the model of computation, various important algorithms cannot be processed directly on such computers, and must be modified. We provide modifications of various existing protocols, including algorithms for universal fault-tolerant computation, Shor's factorization algorithm (which can be extended to any algorithm computing an NP function), and some search algorithms to enable processing them on ensemble quantum computers.

1 Introduction

Quantum computing is a new type of computing which uses the properties of quantum mechanics to suggest fast algorithms to several important problems. For example, Shor's algorithm [21] for factoring large numbers is exponentially faster than any known classical algorithm. Similarly, by utilizing Grover's algorithm [11] it is possible to search a database of size N in time

$O(\sqrt{N})$, instead of $O(N)$ in the classical setting.

NMR computing, first suggested by Cory, Fahmy and Havel [10], and by Gershenfeld and Chuang [9], is currently the most promising implementation of quantum computing, and several quantum algorithms involving only few qubits have been demonstrated in the labs [10, 9, 6, 12, 17]. In such NMR systems, each molecule is used as a computer. Different qubits in the computer are represented by spins of different nuclei. Many identical molecules (in fact, a macroscopic number) are used in parallel; hence, this model is called ensemble or bulk quantum computation model. In such bulk models, qubits in a single computer cannot be measured, and only expectation values of a particular bit over all the computers can be read out¹.

The impossibility of performing measurements on the individual computers causes severe limitations on ensemble quantum computation. It was generally assumed that rather simple strategies of delaying (or avoiding) measurements can be used to bypass these limitations and to enable the implementation of *all* quantum algorithms. We, however, find that for a scalable measurement model such strategies to be *insufficient* for many algorithms (including Shor's factorization algorithm and fault-tolerant computation).

*This work was supported in part by grants from the Revolutionary Computing group at JPL (contract #961360), and from the DARPA Ultra program (sub-contract from Purdue University #530-1415-01).

†E-mail addresses of the authors are, respectively: {boykin, talmo, vwani, vatan}@ee.ucla.edu.

¹Reading the state of n qubits together, as done in many current experiments, is not scalable since it requires distinguishing among 2^n states.

We briefly address other problems related to NMR-computation, namely, the addressing problem and the pseudo-pure-state (PPS) scaling problem, in Appendix A. In the rest of this paper we restrict ourselves to issues related solely to the **ensemble-measurement problem**. While the results here are vital for bulk computation, the specific results obtained regarding universal and fault-tolerant sets of gates might also be important for other implementations of quantum computing devices where delaying measurements is desired.

2 The measurement in ensemble quantum computation

The measurement process in quantum mechanics can be described simply as follows: To measure the state of a qubit, say $|\psi\rangle = \alpha|0\rangle + \beta|1\rangle$ in the computation basis ($|0\rangle; |1\rangle$), one measures the Hermitian operator (the observable) $\sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ to get the outcome $\lambda_0 = 1$ with probability $|\alpha|^2$ and $\lambda_1 = -1$ with probability $|\beta|^2$. In an NMR ensemble model, the corresponding qubit in every computer is measured simultaneously, resulting in the expectation value, i.e., the outcome of the measurement is a signal of strength proportional to $|\alpha|^2 - |\beta|^2$.

Clearly, when the outcome of a measurement is expected to be the same on each of the computers, the ensemble measurement is as good as the standard (single computer) measurement. Usually, this is not the case. Hence, if the measurement process could yield different results for different individual computers, one would expect that the corresponding algorithm will need modifications in order to run on an ensemble computer.

The measurement problem is easily demonstrated in two cases:

Random number generator (RNG): Using a single qubit one can easily create an RNG.

To create a binomial probability distribution with parameter p one prepares a state $\sqrt{p}|0\rangle + \sqrt{1-p}|1\rangle$, and measures in the computational basis to obtain the desired RNG. This, as far as we know, cannot be done on an ensemble quantum computer, where only the expectation value $p\lambda_0 + (1-p)\lambda_1$ can be classically monitored. It is unclear yet, whether any algorithm which uses an RNG as a subroutine can still be operated, e.g., using a qubit in a state $\sqrt{p}|0\rangle + \sqrt{1-p}|1\rangle$ to be a control bit of the entire process that follows the creation of a random number.

Teleportation: Standard teleportation can easily be performed on a three qubit quantum computer, but strictly speaking, it cannot be performed on an ensemble quantum computer. This is because a direct Bell-state measurement of the ensemble quantum computer is computationally useless: each computer will yield a random result (of the Bell measurement), and on average the outcome is $(1/2)\lambda_0 + (1/2)\lambda_1$ for each of the two measured qubits; hence, there is no way to decide how to rotate the third qubit in each individual computer. Yet, a fully-quantum teleportation of the type suggested in [5] can be, and has been [17], performed on ensemble quantum computer: in this fully-quantum teleportation, the measurement of an individual computer is never monitored, and a classically-controlled rotation of the third qubit is replaced by a quantum control operation, in which the control qubits dephase before being used.

The current algorithms, which have several possible measurement outcomes, can be sorted into four groups based on the processing which follows the measurement, and the possibility of avoiding the measurement. When implemented on ensemble computers, each of the four group requires a different adaptation strategy for the algorithm:

1. For a particular “desired” outcome of the entire algorithm, there is more than one “good”/“desired” outcome of an intermedi-

ate measurement. An additional algorithmic step is then used to derive the desired final result, and this algorithmic step can be replaced by a controlled operation [e.g., error-recovery, in which the final result is the corrected qubit; Shor’s factoring algorithm, in which the same candidate for the “order” is obtained from different intermediate measurement outcomes].

2. The algorithm has more than one correct final outcome and no further processing is done [e.g., Grover’s search algorithm with several solutions]
3. The algorithm has more than one final result, and some of the results are bad/undesired solutions. The algorithm is repeated when bad solution is obtained [e.g., a wrong factor obtained in Shor’s factoring algorithm].
4. The measurement step of the algorithm ought to be replaced with available control operations (as in the first case), but such controlled operation cannot be performed [e.g., fault-tolerant universal computation].

The first case was recognized before in the seminal work of Gershenfeld and Chuang [9]. When the outcomes of a measurement on various computers are not the same, it might be the case that the different measurement outcomes can be worked on by a classical algorithm such that a *unique* final answer is obtained. For such algorithms, one can simply delay (or even avoid) the measurements and incorporate the algorithmic step, which follows the measurement, into the quantum algorithm (as a controlled operation). This modified algorithm will now yield a *unique* answer on all the computers. It was generally assumed that such strategies of delaying measurements can be used to save *all* quantum algorithms. In fact, the strategy’s success is restricted only to the cases where the measurements can be delayed, the final outcome

is unique, and the final outcome is always obtained². Indeed this strategy works for the error recovery process. The other cases explained above require major modifications of the algorithms.

In the case of algorithms yielding several final good results (case (2)), we suggest reordering techniques that provide unique solutions. Implementation of search algorithms in the case of multiple solutions on ensemble computers requires such modifications (derived in Section 4.3). We note that for a measurement model where all the 2^n states of an n -qubit system can be distinguished, the multiple-solutions case is not a problem. However, as noted earlier, such a scheme is not practical for any algorithm involving even tens of qubits, and the exponential resolution requirement makes it no better than a classical computer.

In the case of algorithms having good and bad outcomes (case (3)), we show in Section 4.1 cases where we can solve the problem by replacing bad results by random data, which do not interfere with the reading of the good result. Previous work by Gershenfeld and Chuang [9] noted that Shor’s factorization algorithm can be implemented on ensemble quantum computers, by solving the problem as in case (1). However, in addition to problem (1), Shor’s algorithm (on ensemble computer) suffers also from problem (3), and hence the modified algorithm suggested in [9] is not sufficient. Hence, the algorithm requires a further modification (the randomizing-bad-results strategy) in order to work in the general case. Alternatively, one might be able to control-repeat the computation in case the classical verification showed that the algorithm yielded a bad output; unfortunately, such strategy is not easily implementable and cannot be easily justified; furthermore it leads to a much longer computation process, and hence to higher

²Although we use the term “delayed” measurements, in our modified algorithms sometimes the measurements are not needed at all (and not merely delayed).

sensitivity to errors.

Case (4) is of pivotal importance to realistic quantum computation. The schemes proposed so far for quantum fault-tolerant computation usually use an incomplete set of gates, i.e., a set of gates that does not generate a dense subset of the group of unitary operations. In order to complete the set to a universal set, the schemes use interactions with ancilla qubits, which are then measured [22, 15, 19]. Each such measurement is followed by an application of a unitary operation, U_j , that depends on the outcome of the measurement (j). A direct scheme for removing such measurements (followed by the required unitary operations U_j), and replacing them by controlled operations, $\Lambda(U_j)$, will not in general be realizable. This is because, $\Lambda(U_j)$ might not be realizable by the incomplete set of fault-tolerant gates. For example, if one attempts to remove measurements in Shor's scheme for fault-tolerant realization of Toffoli gate [22], then the corresponding controlled operations would itself require Toffoli gates! We believe that this issue was not explicitly addressed in previous works, and we show for the first time how an analysis of error propagation and careful design of classical reversible circuits can allow one to delay measurements in a fault-tolerant manner.

In a prior work, addressing case (4), Aharonov and Ben-Or [1] have observed that the measurements required for fault tolerant computation can be substituted by reversible classical circuits performing controlled operations. In this paper we give an explicit description of this process and study in detail the process of error propagation and how it can be handled in the resulting circuit. Knill, Laflamme, and Zurek [14] followed a different approach that potentially does not require measurements. However, to the best of our knowledge, this approach is incomplete and a proof of universal fault-tolerant computation is not yet available. For example, a measurement-free implementa-

tion of the Hadamard gate using that approach has not been demonstrated.

Finally, Peres [18] also discusses the possibility of measurement-free encoding and decoding procedures in quantum error-correction. However, in his scheme the quantum information is transformed to a single qubit, while we suggest a method that is suitable for fault-tolerant computation.

3 Obtaining a universal and fault-tolerant set of gates

The idea of quantum fault-tolerant computation [22, 1, 15, 13, 19] can be described briefly as follows. Suppose that we have a noisy quantum circuit C which we want to simulate by a fault-tolerant circuit $\tilde{C}$. In one level of such a circuit, the regular bits are replaced by logical bits $|0\rangle_L$ and $|1\rangle_L$, where these are some entangled states of a block of physical qubits. While C operates on data qubits, in the circuit $\tilde{C}$ all operations are performed on encoded data, i.e., each data qubit or a set of data qubits is represented as a block of qubits that belongs to some quantum error-correcting code. Then each operation of C performed by a gate g_j is simulated by a procedure (subcircuit) $\tilde{g}_j$ in the circuit $\tilde{C}$ such that in $\tilde{g}_j$ each computation transforms codewords to codewords. In order to avoid accumulation of errors, after each computation in $\tilde{g}_j$ a "correction procedure" is performed to correct any error that is introduced in that computation. So in the fault-tolerant circuit $\tilde{C}$ each computation step is followed by a correction step.

The operations on the encoded qubits introduce a large number of additional gates and qubits, and unless one is careful, it is possible that more errors are introduced than can be corrected by the code. To avoid any such catastrophic accumulation of errors, it is desirable that the operations in the fault-tolerant circuits prevent "spreading of errors" by making

sure that each gate error causes a single error in each block. It is useful now to review how errors propagate in quantum circuits. For example, consider the CNOT (controlled-not) gate which performs the operation $|a\rangle_c |b\rangle_t \mapsto |a\rangle_c |a \oplus b\rangle_t$ in the computation basis; for the rest of this paper, we shall drop the subscripts c (control) and t (target) and designate the control bit as the one on the left side. Clearly, applying CNOT operation from one bit to many target bits can propagate one bit error from the control bit to all the target bits. On the other hand, applying CNOT from many control bits to one target bit can propagate one phase error from the target bit to all the control bits. It is easy to observe this “back” propagation of the phase errors: if we apply CNOT on the state $(|0\rangle + |1\rangle) \otimes (|0\rangle + |1\rangle)$ and there is a phase error in the target qubit, we will get

$$\begin{aligned} |0\rangle \otimes (|0\rangle - |1\rangle) + |1\rangle \otimes (|1\rangle - |0\rangle) = \\ (|0\rangle - |1\rangle) \otimes (|0\rangle - |1\rangle) \end{aligned}$$

which results in a phase error in the control qubit. Hence, fault-tolerant computation requires that this gate be applied only in the case where the control qubit $|a\rangle$ and the target qubit $|b\rangle$ belong to different blocks. Furthermore, this error-propagation phenomenon is also true for other controlled operations, and this motivated a *sufficient* condition for fault tolerance: only perform bitwise operations or transversal operations on qubits within a code. It is, however, *not* a *necessary* condition for fault-tolerance, and careful constructions may allow one to apply control gates from many control bits onto one target bit, without destroying the fault-tolerant computation, to resolve the catch-22 problem we observe in the following discussions.

To get a quantum fault-tolerant computation, it is enough to show that for a *universal* set of quantum gates the above mentioned procedure on the encoded data is possible. Quantum fault-tolerant schemes usually (see, e.g.,

[22, 19]) depend on measurements to ensure that the set of the operations permissible on encoded data (i.e., codewords in a quantum error-correcting code) is actually a universal set. Some of the gates in the universal set do not require measurements, e.g., the operations H , $\sigma_z^{1/2}$, and CNOT. [For CSS codes [22], each of these logical gates can simply be achieved by performing the same gate bit-wise on the individual qubits (e.g., H is achieved on code words via applying H on individual qubits), but the bit-wise $\sigma_z^{1/2}$ yield a $\sigma_z^{-1/2}$ logical gate, hence requires an additional step of bit-wise σ_z , to yield the desired logical gate.] In existing suggestions (except [14] as previously explained), at least one gate (e.g., Toffoli in [22] and $\sigma_z^{1/4}$ in [4]) requires measurements.

There is always a simple scheme that potentially allows one to postpone measurements of ancilla qubits in quantum computation. Recall that a measurement is followed by an operation U_j , which is a unitary operation performed on the data based on the outcome of a measurement on the ancilla qubits (and U_j can be performed fault-tolerantly using the given, non-universal, set of operations). As explained in Section 2, the scheme for delaying the measurement can be successfully implemented only if the controlled operations $\Lambda(U_j)$ ’s are in the set of *available* measurement-free operations; i.e., these control operations can be implemented on encoded data fault-tolerantly and directly without using any measurements. However, in the cases investigated so far, it is not the case that the required controlled operations $\Lambda(U_j)$ are implementable in a direct fault-tolerant manner. For instance, in Shor’s fault-tolerant set of gates [22], a measurement is required for the preparation of a Toffoli gate, but a Toffoli gate is required if we want to delay that measurement. This is because the measurement is followed by a controlled-NOT operation, and hence can only be replaced by a controlled-controlled-

NOT which is a Toffoli gate. This seems like a catch-22 situation! ³

However, the solution comes from the vital observation that some operations need protection only from the bit errors, and do not need to use full quantum codes.

By replacing the “quantum ancilla” (in a logical basis $|0\rangle_L$ and $|1\rangle_L$) by a “classical ancilla” in a “classical” basis $|\vec{0}\rangle = |0\cdots 0\rangle$ and $|\vec{1}\rangle = |1\cdots 1\rangle$, we can use the classical ancilla to perform $\Lambda(U_j)$ in a fault-tolerant manner, and this can be done in the two cases where the outcomes are the Toffoli gate required for the Shor’s basis, and the $\sigma_z^{1/4}$ gate required for the basis of [4]. One can interpret the classical basis as the classical repetition code. We call the ancilla in these states “classical” since a classical error-correction code can be used to correct bit errors in it. Clearly, phase errors are not corrected in the classical ancilla, yet we found that the use of such a classical ancilla is still good enough for our purpose.

Replacing Measurements of Encoded Ancilla Qubits:

In the following we shall replace the measurement of the quantum ancilla followed by the operation U acting on the quantum data, by a sequence of operation: we copy the two basis states of a quantum ancilla into a classical ancilla, we perform classical error correction on the classical ancilla, and we use the classical ancilla as a control bit for performing the operation $\Lambda(U_j)$ with the quantum data as the target bit.

The measurement of the quantum ancilla in the original protocol is done as follows [19]:

³Similarly, in the fault-tolerant universal set of gates suggested in [4], the generation of the $\sigma_z^{1/4}$ gate without measurements leads to a catch-22 problem; a $\sigma_z^{1/2}$ gate (which follows the measurement) need to be replaced by a $\Lambda(\sigma_z^{1/2})$ gate, which is not available as long as the $\sigma_z^{1/4}$ gate is not available.

measure each of the physical qubits, and perform a classical error correction on the outcome of this measurement to determine the state of the ancilla. For example, if the 7-bit CSS code [22] is used to encode data, then a measurement will yield a possibly corrupted codeword of a classical 7-bit Hamming code. After classical error correction, if the parity of the codeword is “even” then the ancilla has collapsed to the state $|0\rangle_L$, otherwise to the state $|1\rangle_L$. Classical error correction is enough because phase errors before a measurement will not change the outcome probabilities.

As a first step toward removing such a measurement, we propose a new gate that copies an encoded quantum ancilla word onto a classical ancilla:

$$\mathcal{N} : \begin{cases} |0\rangle_L \otimes |\vec{0}\rangle & \longrightarrow |0\rangle_L \otimes |\vec{0}\rangle, \\ |0\rangle_L \otimes |\vec{1}\rangle & \longrightarrow |0\rangle_L \otimes |\vec{1}\rangle, \\ |1\rangle_L \otimes |\vec{0}\rangle & \longrightarrow |1\rangle_L \otimes |\vec{1}\rangle, \\ |1\rangle_L \otimes |\vec{1}\rangle & \longrightarrow |1\rangle_L \otimes |\vec{0}\rangle. \end{cases} \quad (1)$$

Let $\mathcal{N}$ be a unitary operation that implements the above transformation. [We show in the next subsection that this operation can be done fault-tolerantly.]

With this operation ($\mathcal{N}$), the quantum bit is “copied” onto the classical ancilla. Since the repetition code can only correct for bit errors in the classical ancilla, one must make sure that the classical ancilla can still be used to perform $\Lambda(U_j)$ without putting the quantum data in jeopardy. This, however, is not a problem, since phase errors are transmitted from *target* bit to control bit, hence cannot be transmitted from the classical ancilla (control) to the quantum data (target). This leads to the most interesting and possibly counter intuitive aspect of our scheme: the data in the classical repetition code, or any classical function of this data, *can* act as control bits in a bitwise controlled- U operation onto quantum data.

We shall show later two cases where indeed the operations between the classical ancilla and

Figure 1: The operation $\mathcal{N}_1$. Note that the circuit shows the generation of only one classical target bit $|b\rangle$; the operations on the last bit have to be repeated to generate multiple target bits.

the quantum data can be performed bit-wise while the same operations cannot be performed bit-wise between quantum ancilla and the quantum data (as the naive solution of delaying measurements would have suggested).

Note that the quantum data may add phase errors to the repetition code, but that is of no concern to us, since also in the “measured” case, the classical repetition code has lost phase coherence. If there are t bit errors in the repetition code, it will result in t errors in the quantum data. Fortunately, bit errors *are* corrected in the repetition code. Hence, *the operation $\mathcal{N}$ enables one to create universal bases without measurement.*

The operation $\mathcal{N}$: quantum-to-classical controlled–NOT. In Figure 1, we represent a circuit that computes operation $\mathcal{N}_1$ for the seven-bit CSS code, where $\mathcal{N}_1$ stands for Eq.(1) with only one bit of the classical ancilla. The syndrome ancilla bits are used to prevent the spread of one bit error from the quantum ancilla into the classical bit. Only two errors (in any of the inputs, the gates or the time steps) shall yield an error in the classical bit.

This is not the complete circuit; in the complete circuit, the same computation on the bottom four bits is repeated n times, where n is the number of qubits in a codeword. At each repetition stage the syndrome bits are discarded, and another bit b_i is created ($1 \leq i \leq n$). In principle, the syndrome bits could be ignored, reset, or measured. These bits will not effect the operation beyond their use as a form of error detection in the codeword. The bits b_i are then corrected (to yield the classical 0 or 1) using a majority vote.

The circuit $\mathcal{N}_1$ flips the bit b if the quantum ancilla (acting here as a control bit) is $|1\rangle_L$, and does nothing otherwise. This circuit operates properly as long as there is up to one bit error in the quantum data (there can actually be an unlimited number of phase errors). Note that phase errors in the lower part will spread to the quantum ancilla; however, this is of no consequence, since the quantum ancilla never interact with the quantum data in later stages. Bit errors in the quantum ancilla are important, since the process is repeated n times, hence bit errors, created in the quantum ancilla at initial stage of $\mathcal{N}_1$, will spread errors into the next bits

Figure 2: Preparing an eigenvector.

Figure 3: Fault-tolerant $\sigma_z^{1/4}$ without measurement.

of the classical ancilla. Fortunately, bit errors are not transmitted from the classical to quantum section, and the quantum ancilla cannot be disturbed by a bit error in bits of the classical ancilla or the syndrome ancilla. If there is one error in the $|0\rangle$ bits used to store the syndrome it will cause an error in the single classical bit. But such errors must be overcome by repeating this circuit n times with fresh syndrome bits for each repetition. At that point we will have a repetition code that will successfully recover from k' errors. Once this number k' is equal to, or greater than, the number of errors, k , that the *quantum* code can correct for, we may stop. For a probability p of an error (per gate, per input bit, and per delay line) the resulting error rate of this circuit is $O(p^2)$, as required for fault tolerant computation. The threshold can easily be calculated by counting the potential places for two errors, and the threshold can be much improved by enhancing the parallelism, and by repeating $\mathcal{N}_1$ only $2k+1$ times (e.g., with the 7-bit quantum code, that is $n=7$, which corrects $k=1$ error, it is enough to repeat the circuit

3 times, correct the outcome using a majority vote, and then copy the result into seven bits).

Any required classical reversible fault-tolerant calculation can be performed on the classical ancilla. Finally, it is used as control bits in bitwise operations back onto the quantum data.

Creating the special states required for fault-tolerant universal computation, without using a measurement

Our method is general and can be described as follows. Assume that a quantum code of length n is used for encoding data. Suppose that $U \in \mathbf{U}(2^l)$ [for our purpose it is enough to consider up to three qubits ($l=3$) operations], and $\tilde{U} = U^{\otimes n}$ is the unitary operation on the codewords obtained by applying U bitwise. Suppose that $\tilde{U}$ has eigenvectors $|\phi_0\rangle$ and $|\phi_1\rangle$ such that

$$\tilde{U}|\phi_0\rangle = |\phi_0\rangle \quad \text{and} \quad \tilde{U}|\phi_1\rangle = -|\phi_1\rangle.$$

Then the quantum circuit in Figure 2 outputs the eigenvector $|\phi_0\rangle$ if the input state is

$\alpha|\phi_0\rangle + \beta|\phi_1\rangle$ (for any α, β). In this figure $\tilde{U}_{\text{flip}}$ is a unitary operation that maps $|\phi_0\rangle$ on $|\phi_1\rangle$ and vice versa. The operations $\Lambda(\tilde{U})$ (i.e., the controlled- $\tilde{U}$), and H are applied bitwise. The last two controlled operations will be explained in the sequel.

This scheme is practical if it is possible to prepare a state $\alpha|\phi_0\rangle + \beta|\phi_1\rangle$, where it does not matter what is the values of α and β . In this circuit the first line is a single parity bit, each of the second and third inputs is a block of n qubits, containing the cat-states lines and the special state lines respectively. The third gate, the controlled-not gate which we call here P , is a Parity gate which calculates the parity of the cat-state lines and puts the result in the parity bit. It is done by a sequence of controlled-not from each control bit onto one target bit. The figure only demonstrates the creation of one parity bit $|\phi_0\rangle$ in an unprotected manner (as far as a bit error in the parity bit is of concern). The real circuit is a bit different: The operations $\Lambda(\tilde{U})$, H and P , are repeated n times, each time with fresh cat-states and fresh parity bit (but on the same special state's lines). Then a majority vote is calculated on the parity bits, in order to reduce the probability that an error in a cat state or in the parity bit will ruin the result. Then the n parity results are corrected, so that the probability of two errors becomes low [that is, of order $O(p^2)$]. Finally, the parity result is used to control $\tilde{U}_{\text{flip}}$ in a bit-wise manner, so that the special state is created via a fault tolerant operation.

Fault-tolerant $\sigma_z^{1/4}$ without measurement.

Let $\mathcal{B}$ be the basis consisting of H (Hadamard), $\sigma_z^{1/2}$, and CNOT. The operations in $\mathcal{B}$ are fault-tolerant, simply because they can be applied to encoded data bitwise (when standard codes are used). But $\mathcal{B}$ is not universal. One way to make $\mathcal{B}$ universal is to add the Tof-

foli gate to it. Another way is to add the gate $\sigma_z^{1/4}$, as shown in [4]. The advantages of this latter set of gates are that it is (a) simple to be implemented, (b) simple to be proven universal, and (c) simple to operate with delayed measurements.

We show here how it is possible to implement this operation on codewords without using any measurement. This scheme is a modified version of the original method for implementing $\sigma_z^{1/4}$ on codewords [4], and it does not use measurements.

First, we need to prepare the following state

$$|\psi_0\rangle = \frac{1}{\sqrt{2}} \left(|0\rangle_L + e^{\frac{i\pi}{4}} |1\rangle_L \right).$$

This state can be prepared with a circuit of form given in Figure 2. For this purpose, let $U = e^{\frac{i\pi}{4}} \sigma_x \sigma_z \sigma_z^{1/2}$ and $|\psi_1\rangle = \frac{1}{\sqrt{2}} \left(|0\rangle_L - e^{\frac{i\pi}{4}} |1\rangle_L \right)$. Then $\tilde{U}|\psi_0\rangle = |\psi_0\rangle$, $\tilde{U}|\psi_1\rangle = -|\psi_1\rangle$, and $U_{\text{flip}} = \sigma_z$.

Now we are ready to describe the fault-tolerant $\sigma_z^{1/4}$ without measurement. Then the circuit in Figure 3 shows the fault-tolerant implementation of $\sigma_z^{1/4}$ on a codeword $|x\rangle_L$. In this circuit, $\mathcal{N}$ is the unitary operation defined in (1). Apart from replacing the standard measurements by the $\mathcal{N}$ circuit, this figure is exactly the same as the one drawn in [4] to implement the $\sigma_z^{1/4}$ gate. In this figure each input in fact denotes a block of qubits, and operations are bitwise.

Fault-tolerant Toffoli without measurement.

The more conventional (and more complicated) set of universal fault-tolerant gates contain the Toffoli instead of the $\sigma_z^{1/4}$.

We show explicitly how to implement Toffoli on encoded data without using any measurement. This scheme is a modified version of Shor's original method for implementing Toffoli

a random number x and tries to find the least positive integer r such that $x^r \equiv 1 \pmod{n}$. This least r is the *order* of $x \bmod n$, and n can be factored with a high probability, once r is known.

Shor's algorithm does not yield r directly (in the quantum process). Instead, another integer c is the actual outcome of the quantum protocol, from which the right r can *sometimes* be obtained by a classical algorithm. Let us call the outcome of the classical algorithm r' ; in at least $O(1/\log \log n)$ fraction of the cases, the number r' is the desired r , and whether it is the case or not is checked via a classical algorithm. Let the probability of a correct result (on an individual computer) be p_r . While the order r (for a given x and n) is unique, the result c and the calculated r' are not unique. Having several good outcomes c_i does not cause a problem (as noted by in [9]), since the quantum computer can perform a classical algorithm which calculates r from any of the possible c_i . However, this operation by itself is not sufficient, since many of the computers (probably, most of them) give an outcome r' which is not the correct r . When expectation values are measured for the j th bit, the correct result r_j happens with small probability p_r , and hence it is obscured by the wrong results r'_j .

If the measurement process could distinguish among 2^n states of an n -qubit system (which will require exponential resolution), then one could read the correct result accurately. However, such an operation is not permitted, and hence the technique of [9] is not sufficient. Another potential situation, which could also lead to a simple resolution, is if the wrong- r results are well distributed (e.g., totally random); in such a case, on the average these wrong- r results will cancel out (e.g., average to yield zero) and will not obscure the correct result. Let us show that this is not always the case, and that the bad results are not always averaged to zero, and hence the good result sometimes is indeed

obscured.

The output c of the quantum process in Shor's algorithm is used to calculate the order r [21]. For this, the integers d' and r' are found such that

$$\left| \frac{c}{q} - \frac{d'}{r'} \right| \leq \frac{1}{2q},$$

where $n^2 < q \leq 2n^2$, and q is a power of 2. Then the fraction d'/r' is unique. The integer r' is the output of the algorithm as the desired order (which is actually r). To continue, let $\alpha(c)$ be the unique integer such that $-q/2 \leq \alpha(c) \leq q/2$ and $rc \equiv \alpha(c) \pmod{q}$. One of the possible situations that leads to incorrect answer is that the output c of the quantum process satisfies the condition

$$\left| \frac{c}{q} - \frac{d}{r} \right| \leq \frac{1}{2q},$$

and d and r are not relatively prime. Then the answer, instead of r , would be a divisor of r . The probability that such event occurs is (see [21]) approximately $4(r - \phi(r))/(\pi^2 r)$. This probability can be some constant far away from zero. For example, if $r = 2^s 3^t$, then $\phi(r) = r/3$ and the probability the algorithm provides a divisor of r is ≈ 0.135 .

Let us now present a modified factorization protocol that bypasses this ensemble measurement problem. The idea is to replace an additional part of the classical protocol, a part which verifies that r is indeed the order, by a quantum one. Also, a simple (but crucial) modification of the protocol is required. Let the register holding the result (r or r') be called s_1 . Let us use an additional register s_2 of the same number ℓ of qubits as s_1 . Let the register s_2 be in the state

$$H|0\rangle \otimes H|0\rangle \otimes \cdots \otimes H|0\rangle = \frac{1}{2^{\ell/2}} \sum_{x \in \{0,1\}^\ell} |x\rangle, \quad (3)$$

where $H|0\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$. Now we augment the quantum factorization algorithm with the

following procedure. When the original factorization algorithm finishes, test the result in the register s_1 to see whether it gives the correct value of the order r . If the result on the i th computer is indeed the order then nothing is to be done and the outcome r is kept in s_1 . Whenever the result is an incorrect value r' , swap the contents of the registers s_1 and s_2 so the outcome r' is replaced by the state $H|0\rangle \otimes \cdots \otimes H|0\rangle$ which yields a completely randomized outcome once it is measured. Now, a measurement of the j th bit on s_1 will give the correct result if the string holds the state r or it yields zero (on average) if the string originally contained the wrong result r' .

Although the strength of the good signal may be small, there are enough computers running in parallel to read it since in the worst case, it is only logarithmically small.

4.2 Algorithms for NP functions

Technique used in the previous section for Shor’s algorithm can easily be generalized to any quantum algorithm that computes an NP function. By an *NP function* we mean a function whose graph is in the class P. More specifically, a function $f : \Sigma^* \rightarrow \Sigma^*$, for some alphabet Σ , such that there is a polynomial-time Turing machine that for $x, y \in \Sigma^*$ decides whether $f(x) = y$ or not.

4.3 The search algorithm

Certain search operations in a database can be done more efficiently on a quantum computer than on a classical computer [11]. Here the search means to find some item x in the database such that x satisfies some predefined condition T ; i.e., we are looking for the solutions of $T(x) = 1$. The analysis of [3] shows that if the size of the database is N and the number of solutions are t , Grover’s algorithm, with high probability, can find a solution in time

$(O\sqrt{N/t})$. When there is only one solution, this algorithm yields the desired result also on an ensemble computer.

However, when several (say $t \geq 2$) different items satisfy the required condition, the protocol will randomly yield one of them. Therefore, in this case the algorithm is not suitable for ensemble computation. We show here how this algorithm can be modified such that ensemble computation still provides a correct solution with high probability.

We assume t , the number of solutions, is *known* and *constant* (the general case will be studied in the next section). We first consider the case $t = 2$. When processed on an ensemble-measurement computer, only expectation values are obtained, and the two outcomes partially obscure each other to yield zero (as the average expected value) for j th bit of the answer if the j th bits of the two solutions are different.

To solve this problem we suggest to hold several (say m) computers in one molecule. After each computer in the molecule finishes Grover’s algorithm, the procedure is continued by sorting the outputs of different computers in an increasing order. Finally let the algorithm contain a step where the first and the last results are compared, and if they are equal then both are replaced by a randomized data (3), as in the modified Shor’s algorithm. Once the first and last computers hold different outcomes, we are promised that the small solution is always the first, and that the large solution is always the last. Thus, we can obtain both solutions.

The probability that the first and the last solutions are the same is $\frac{1}{2^m}$, so the final outcome is obtained with probability exponentially close to one. Even without applying the randomization to the bad outcomes, the expected outcomes are still readable.

When $t > 2$, we apply the same procedure (without randomization to the bad outcomes). We still reorder the solutions so that the minimal solution is in the first position. However,

we might obtain different minimal solutions for different molecules. The probability of failing to obtain the global minimum solution in the first position is $(1 - \frac{1}{t})^m$, and as long as it is small (say less than $e^{-\lambda}$, which holds if $m > \lambda t$) the protocol can work properly. Note that this modified algorithm still works in time $O(\sqrt{N}/t)$.

Only the smallest and largest solutions can be obtained by the above method. If one needs the other solutions, these can easily be obtained via similar methods, once some solutions are already known.

4.4 Search algorithm: the case of unknown number of solutions

Now we consider the most general case. Here we do not assume any condition on t , the number of solutions; it can be known or unknown, large or even zero. Our method is based on a binary search. We also utilize the following fact established in [3]: Let $\mathcal{B}$ be a database of size M ; then the search algorithm, with high probability, starting with the input $\frac{1}{\sqrt{M}} \sum_{x \in \mathcal{B}} |x\rangle$ in time $O(\sqrt{M})$ can determine whether there is any solutions in $\mathcal{B}$ or not.

Without loss of generality, we can assume that the database is represented as the members of the unit cube $V = \{0, 1\}^n$. So $N = 2^n$. For any string $\alpha = (\alpha_1, \dots, \alpha_k) \in \{0, 1\}^k$, let V_α be the subset of V consisting of all strings $(\alpha_1, \dots, \alpha_k, x_{k+1}, \dots, x_n)$; i.e., V_α contains all strings in V that start with α . Thus $|V_\alpha| = 2^{n-k}$.

Our algorithm first checks whether there is a solution or not. If there is no solution then it stops. Otherwise it runs in n stages. The output of the stage j is a database $\mathcal{B}_j$ of size 2^{n-j} which contains a solution. At the end $\mathcal{B}_n = \{\xi\}$, where ξ is a solution. The algorithm starts with the database $\mathcal{B}_0 = V$. It checks whether there is any solution in V_0 . If there is a solution then $\mathcal{B}_1 = V_0$, otherwise $\mathcal{B}_1 = V_1$. In a general stage $j + 1$, the input is of the form $\mathcal{B}_j = V_{\alpha_j}$

where $\alpha_j \in \{0, 1\}^j$, and there is a solution in $\mathcal{B}_j$. Then the algorithm checks whether there is a solution in $V_{\alpha_j 0}$, if so then the output of this stage is $\mathcal{B}_{j+1} = V_{\alpha_j 0}$, otherwise the output is $\mathcal{B}_{j+1} = V_{\alpha_j 1}$. This completes the description of our search algorithm. It is easy to check that this algorithm always provides the *first* solution in the lexicographic order. So we have presented a quantum search algorithm that always gives a unique output, no matter how many solutions are there. This is an algorithm which can be implemented on an ensemble-measurement computer. Note that the running time of this algorithm is

$$O(\sqrt{2^n} + \sqrt{2^{n-1}} + \dots + \sqrt{2}) = O(\sqrt{N}).$$

5 Error-recovery in the error-correction process

Standard error correction can be viewed as a computation with more than one good answer, and thus belongs to Case (1) discussed in Section 2. In this case, the syndrome of the error is not unique. In the standard prescription, measurement is used to collapse the ancilla qubits containing the error information. Then these syndrome bits are processed by a classical reversible algorithm to determine the errors, and a unitary operation to correct the error is applied to the data qubits by the output bits of the classical algorithm. In the measurement-free case, the ancilla qubits need not be measured, and the classical subroutine (following the measurement) could be incorporated into the original quantum algorithm.

One can easily verify that the above-mentioned classical subroutine (that processes the ancilla qubits) needs to use Toffoli gates. Using the techniques of Section 3 one could implement a quantum Toffoli gate without measurements, and hence, there is no fundamental problem in having a single quantum code for the

measurement-free circuit. However, implementing a quantum Toffoli gate fault tolerantly and without measurement is an involved process. Fortunately, the techniques of Section 3 can be also applied so that the classical subroutine is carried out on a classical code. The state of the ancilla qubits can be first copied onto a classical repetition code using the $\mathcal{N}$ gate. Now classical reversible computation can be performed on the repetition code and then a control operation can be performed on the quantum data to correct for the errors. Since phase errors from the classical subcircuit will not propagate to the quantum data, using repetition codes to correct for any bit errors in the subcircuit is sufficient. This technique thus allows one to fault-tolerantly replace quantum Toffoli gates by classical ones in the error recovery process.

6 concluding Remarks

To summarize, we showed that running algorithms on bulk (ensemble) computers is not always obvious. We modified various important algorithms so that they can run on ensemble computers.

More work is required in order to run algorithms without measurement with only near-neighbor interactions, and more work is required to solve the addressing and scaling problems.

We are thankful to Dorit Aharonov for many helpful remarks.

APPENDIX A

As mentioned in the introduction, in NMR computing, each molecule is used as a computer, and different qubits in one computer are spins of different nuclei. Many identical molecules are used (a macroscopic number) in parallel. Moreover, the state of the qubits is initially a thermal mixture.

There are three main problems with the current proposals for NMR computers [23, 7]: the ensemble-measurement problem, the addressing problem, and the pseudo-pure-state scaling problem. Unless these problems can be solved or mitigated, it is widely believed that NMR computing will not be very useful as a future computing device. As we demonstrate in this paper, the ensemble-measurement problem can be addressed successfully. While the other two problems are challenging, we argue in the following paragraphs that recent advances do hold the promise of mitigating their effects, and that further research is required before one can conclude whether NMR/ensemble quantum computing can indeed be scaled up to perform practical quantum computation.

The addressing problem: The individual qubits in an NMR computing system cannot be accessed by a laser directed only to it, and hence different level separation is usually used for each of the qubits. For n qubits (with only near-neighbor interactions) there is a need for $O(n)$ different laser frequencies, and off-resonance effects become non-negligible. A solution to this

problem was suggested in [16], where a chain of three different types of qubits, arranged in the form of $ABCABCABC\dots ABC$ is used. In this chain one (and only one) of the qubits, say of type B , is replaced by a pointer-qubit of a fourth type D . Now, with only five swaps operations: $\text{swap}(AB)$, $\text{swap}(CA)$, $\text{swap}(BC)$, $\text{swap}(AD)$, $\text{swap}(DC)$, and with three operations on the pointer and its neighborhood: individual qubit rotations $R(D)$, and two-qubit operations $U(AD)$ and $U(CA)$, algorithms can run with only a polynomial slowdown. Thus, in principle, universal quantum computation can be performed on an NMR system with only a constant number of laser frequencies.

The pseudo-pure-state scaling problem: The state of the qubits in an NMR computer is highly mixed. It is a thermal mixture so that the qubits are in a state that is $|0\rangle$ with probability $\frac{1+\epsilon}{2}$ and in a state which is $|1\rangle$ with probability $\frac{1-\epsilon}{2}$, where ϵ is a function of the temperature and the applied strong magnetic field. For the quantum computation model, however, it is assumed that initially all its qubits are in a known state, which, without loss of generality, is assumed to be the state $|0\rangle$. In the existing literature (and current experiments), a novel purification technique was used, which creates a “pseudo-pure-state”, that is, a state which can be written as a mixture of the identity and a pure state. Then, the algorithmic steps are performed on the “pseudo-pure state”. While this ingenious technique allows one to perform entanglement manipulation and demonstrate quantum algorithms involving a few qubits, it has an inherent limitation. In particular, there is an information loss in the process of mixing (via a non-unitary operation) of all eigenstates except the state $|000\dots 0\rangle$ (see, for example, [9] for detailed explanations), leading to an exponential decrease in signal-to-noise ratio with the increase in the number of qubits. Hence, the current pseudo-pure state approaches cannot be scaled up, and thus they

lose any potential advantage over classical computers. It is worth observing, however, that the exponential loss of signal is *an artefact of the existing pseudo-pure state approaches*, and is *not inherent to NMR or ensemble quantum computing*. For example, a simple information-theoretic analysis suggests that $k = O(n\epsilon^2)$ pure qubits can be distilled from n thermal qubits, which are highly mixed. This idea was analyzed further in [20], where an algorithm for extracting $O(n\epsilon^2)$ pure qubits from a thermal mixture of n qubits was suggested. While the solution of [20] is good only when n is large compared to ϵ^2 , it clearly proves the point that methods for creating much better pseudo-pure states probably exist, and that the scaling problem should certainly not discourage scientists from pursuing ensemble quantum computation. We are currently working on this problem and the initial results are very promising.
